Attributing Effects to Interactions

Tyler J. VanderWeele and Eric J. Tchetgen Tchetgen

Abstract: A framework is presented that allows an investigator to estimate the portion of the effect of one exposure that is attributable to an interaction with a second exposure. We show that when the 2 exposures are statistically independent in distribution, the total effect of one exposure can be decomposed into a conditional effect of that exposure when the second is absent and also a component due to interaction. The decomposition applies on difference or ratio scales. We discuss how the components can be estimated using standard regression models, and how these components can be used to evaluate the proportion of the total effect of the primary exposure attributable to the interaction with the second exposure. In the setting in which one of the exposures affects the other, so that the 2 are no longer statistically independent in distribution, alternative decompositions are discussed. The various decompositions are illustrated with an example in genetic epidemiology. If it is not possible to intervene on the primary exposure of interest, the methods described in this article can help investigators to identify other variables that, if intervened upon, would eliminate the largest proportion of the effect of the primary exposure. (Epidemiology 2014;25: 711–722)

In some settings, the effect of a particular exposure may be substantially altered in the presence or absence of a second exposure, so that some form of interaction exists between these 2 exposures. In such cases, it may be of interest to determine the extent to which the overall effect of the primary exposure of interest is due to the presence of the secondary exposure and the primary exposure’s interaction with it. We present an analytic framework within which to address such questions. We show that, if the distributions of the 2 exposures are statistically independent in the population, then the overall effect of the primary exposure can be decomposed into 2 components: the first being the effect of the primary exposure when the secondary exposure is removed, and the second being a component due to interaction. Such decompositions can be useful in settings in which it is not possible to intervene on the primary exposure of interest and an investigator is interested in trying to identify other variables that, if intervened upon, would eliminate much or most of the effect of the primary exposure of interest. We show how this decomposition applies on an additive scale and on a risk ratio scale, and how regression models can be used to estimate each of the components. We discuss extensions to settings in which the 2 exposures are not independent in distribution but rather when one affects the other, and we also discuss a decomposition of joint effects of both exposures and relate these to Rothman’s measures of the attributable proportion due to interaction.

DEFINITIONS AND NOTATION

We will let G and E denote 2 exposures of interest. These may be genetic and environmental exposures, respectively, but they could also both be genetic or environmental, or one or both could be behavioral. We will, for simplicity in exposition, refer to the first as a genetic exposure and the second as an environmental exposure. When the ordering of the exposures is relevant, we will assume that G precedes E. We will assume for simplicity that both exposures are binary; however, we consider more general settings in the Appendix.

Let Y be an outcome of interest that may be binary or continuous. When the outcome is binary, for variable(s) X, we will use \( p_x = P(Y = 1 | X = x) \) to denote the probability of the outcome conditional on \( X = x \). If the effect of \( G \) on \( Y \) is unconfounded, then \( p_{ge1} - p_{ge0} = P(Y = 1 | G = 1, E = 1) - P(Y = 1 | G = 0, E = 1) \) would equal to the effect of \( G \) on \( Y \). If the effect of \( E \) on \( Y \) is unconfounded, then \( p_{ge1} - p_{ge0} = P(Y = 1 | G = 1, E = 0) - P(Y = 1 | G = 0, E = 0) \) would equal to the effect of \( E \) on \( Y \). In the exposition in the text, we will assume that there is no confounding for the effects of \( G \) and \( E \) on \( Y \), but in the appendix we consider analogous results when the effects are unconfounded only conditional on some set of covariates \( C \).

With a binary outcome, we will also use \( p_{ge} = P(Y = 1 | G = g, E = e) \) to denote the probability of the
outcome when \( G = g \) and \( E = e \). The standard interaction contrast on the additive scale would be written as \( (p_{11} - p_{10} - p_{01} + p_{00}) \) and assesses the extent to which the effect of both exposures together exceeds the effect of each considered separately.

**ATTRIBUTING TOTAL EFFECTS TO INTERACTIONS UNDER INDEPENDENCE**

Suppose now that the 2 exposures \( G \) and \( E \) are statistically independent in distribution in the population and suppose that the effects of \( G \) and \( E \) on \( Y \) are unconfounded. We show in the Appendix that:

\[
(p_{e1} - p_{e0}) = (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00}) P(G = 1).
\]

We can decompose the overall effect of \( E \) on \( Y \) into 2 pieces. The first piece is the conditional effect of \( E \) on \( Y \) when \( G = 0 \); the second piece is the standard additive interaction, \( (p_{11} - p_{10} - p_{01} + p_{00}) \), multiplied by the prevalence of \( G = 1 \). We can then attribute the total effect of \( E \) on \( Y \) to the part that would still be present if \( G \) were 0 (this is \( p_{01} - p_{00} \)) and to a part that has to do with the interaction between \( G \) and \( E \) (this is \( p_{11} - p_{10} - p_{01} + p_{00} \)) multiplied by the prevalence of \( G = 1 \). If we could set the genetic exposure to 0, we would remove the part that is due to the interaction and would be left with only \( p_{01} - p_{00} \).

Since we can do this decomposition, we might define a quantity \( pAI_{G=0}(E) \) as the proportion of the overall effect of \( E \) that is attributable to interaction, with a reference category for the genetic exposure of \( G = 0 \), as

\[
pAI_{G=0}(E) = \frac{(p_{11} - p_{10} - p_{01} + p_{00}) P(G = 1)}{(p_{e1} - p_{e0})}.
\]

The remaining portion \( (p_{01} - p_{00})/ (p_{e1} - p_{e0}) \) is the proportion of the effect of \( E \) that would remain if \( G \) were fixed to 0. The proportion attributable to interaction could then be interpreted as the proportion of the effect of \( E \) we would eliminate if we fixed \( G \) to 0.

If \( Y \) is continuous, again assuming that \( G \) and \( E \) are independent, we have a similar decomposition, \( \mathbb{E}[Y|E = 1] - \mathbb{E}[Y|E = 0] = \mathbb{E}[Y|G = 0, E = 1] - \mathbb{E}[Y|G = 0, E = 0] \)

\[
\begin{align*}
&\left[ \mathbb{E}[Y|G = 1, E = 1] - \mathbb{E}[Y|G = 1, E = 0] \right] \\
&- \mathbb{E}[Y|G = 0, E = 0] + \mathbb{E}[Y|G = 0, E = 1] P(G = 1), \text{ and we} \\
&\left[ -\mathbb{E}[Y|G = 0, E = 1] + \mathbb{E}[Y|G = 0, E = 0] \right] P(G = 1)
\end{align*}
\]

could likewise define the proportion attributable to interaction by:

\[
pAI_{G=0}(E) = \frac{\left[ \mathbb{E}[Y|G = 1, E = 1] - \mathbb{E}[Y|G = 1, E = 0] \right] - \mathbb{E}[Y|G = 0, E = 1] + \mathbb{E}[Y|G = 0, E = 0] P(G = 1)}{\mathbb{E}[Y|E = 1] - \mathbb{E}[Y|E = 0]}.
\]

The 2 components of the decomposition: the portion due to interaction and the portion due to the effect of \( E \) when \( G \) is fixed to 0 also have an intuitive form within a regression framework.

Consider the following regression model in which \( Y \) might be binary or continuous:

\[
\mathbb{E}[Y|G = g, E = e] = \alpha_0 + \alpha_g + \alpha_2 e + \alpha_3 e g.
\]

We show in the Appendix that irrespective of whether the outcome is binary or continuous, if \( G \) and \( E \) are independent, then the total effect of \( E \) on \( Y \) is given by \( \alpha_2 + \alpha_3 P(G = 1) \), the portion due to interaction is equal to \( \alpha_3 P(G = 1) \), and the portion due to the effect when \( G \) is fixed to 0 is equal to \( \alpha_2 \). Thus, the proportion due to interaction is simply

\[
pAI_{G=0}(E) = \frac{\alpha_3 P(G = 1)}{\alpha_2 + \alpha_3 P(G = 1)}.
\]

The portion due to the effect when \( G \) is fixed to 0 is simply the main effect of \( E \) in the regression model, \( \alpha_2 \). The portion due to interaction is just the product coefficient \( \alpha_3 \) multiplied by the probability that \( G \) = 1.

Note that under the assumption that \( G \) and \( E \) are independent, the roles of \( G \) and \( E \) can be interchanged. Thus, with a binary outcome we could likewise decompose the total effect of \( G \) on \( Y \) by:

\[
(p_{g=1} - p_{g=0}) = (p_{10} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00}) P(E = 1).
\]

We could define the proportion of the effect of \( G \) that is attributable to interaction (with a reference category for \( E \) of \( E = 0 \)) as \( pAI_{E=0}(G) = \frac{(p_{11} - p_{01} - p_{00} + p_{00}) P(E=1)}{(p_{g=1} - p_{g=0})} \). Expressed in terms of the coefficients of the regression model in (1), we have

\[
pAI_{E=0}(G) = \frac{\alpha_3 P(E = 1)}{\alpha_2 + \alpha_3 P(E = 1)}.
\]

To the best of our knowledge, this approach has not been previously described. The approach we have been considering thus far has assumed that the 2 exposures \( G \) and \( E \) are independent. As we will see later in the article, the decomposition becomes somewhat more complicated when \( G \) and \( E \) are no longer independent in the population as would be the case if one exposure affected the other. Even under independence, the implications of the approach are also sometimes more subtle than they first appear. From the formulae above, the proportion attributable to interaction depends on the main effect coefficient for the primary exposure of interest, the interaction coefficient, and the prevalence of the secondary exposure. Because of this, it would, for example, be possible for the main effect of \( G \), namely \( \alpha_2 \), to be larger than the main effect of \( E \), \( \alpha_3 \), while still also being the case that the proportion of the effect of \( G \) attributable to the interaction is larger than the proportion of the effect of \( E \) attributable to interaction. This could occur, for instance, if the prevalence of \( G \) was relatively small with the prevalence of \( E \) being comparatively larger.
ATTRIBUTING TOTAL EFFECTS TO INTERACTIONS ON THE RATIO SCALE

Often, when an outcome is binary, a ratio scale is used to measure effects. We can define the relative risk for \( G \) as

\[
RR_{g=1} = \frac{P_{g=1}}{P_{g=0}} = \frac{P(Y = 1|G = 1)}{P(Y = 1|G = 0)}
\]

Likewise, we can define the relative risk for \( E \) by

\[
RR_{e=1} = \frac{P_{e=1}}{P_{e=0}} = \frac{P(Y = 1|E = 1)}{P(Y = 1|E = 0)}
\]

We can also define relative risks when \( G \) and \( E \) are considered together; we would define the relative risk for the outcome \( Y \), comparing \( G = g; E = e \) to the reference category \( G = 0; E = 0 \), as

\[
RR_{ge} = \frac{P_{ge}}{P_{g0}} = \frac{P(Y = 1|G = g, E = e)}{P(Y = 1|G = 0, E = 0)}
\]

It is shown in the Appendix that if \( G \) and \( E \) are independent, then we have the decomposition of the excess relative risk for \( E \) as:

\[
(RR_{e=1} - 1) = \kappa(RR_{01} - 1) + \kappa(RR_{11} - RR_{00} - RR_{01} + 1)P(G = 1)
\]

where \( \kappa \) is a scaling factor given by \( \kappa = \frac{P_{00}}{P_{e=0}} \). As on the difference scale, so also on the ratio scale, we can decompose the excess relative risk for \( E \) into 2 components: the first component is the excess relative risk for \( E \) if \( G \) were fixed to 0, \( (RR_{01} - 1) \), and the second component is a portion of the effect due to interaction, \( (RR_{11} - RR_{00} - RR_{01} + 1)P(G = 1) \). The contrast, \( (RR_{11} - RR_{00} - RR_{01} + 1) \), is sometimes referred to as the “relative excess risk due to interaction” (RERI) or the “interaction contrast ratio.”

One of the motivations often given for studying interactions is sometimes referred to as the “relative excess risk due to interaction” (RERI)3 or the “interaction contrast ratio.” We can thus re-express the decomposition above as:

\[
(RR_{e=1} - 1) = \kappa(RR_{01} - 1) + \kappa(RERI)P(G = 1)
\]

The scaling factor forms a part of both portions, \( \kappa(RR_{01} - 1) \), and \( \kappa(RERI)P(G = 1) \), of the total effect, but if we consider the proportion of the effect of \( E \) attributable to interaction, then the scaling factor drops out and we obtain:

\[
pAI_{G=0}(E) = \frac{(RERI)P(G = 1)}{(RR_{01} - 1) + (RERI)P(G = 1)}
\]

By symmetry, a similar decomposition holds for the overall effect of \( G \) on \( Y \) on the risk ratio scale and we have the proportion of the effect of \( G \) attributable to interaction as

\[
pAI_{E=0}(G) = \frac{(RERI)P(E = 1)}{(RR_{10} - 1) + (RERI)P(E = 1)}
\]

Often a logistic regression model is used in analyzing data with a binary outcome on the ratio scale. Consider the logistic regression model

\[
\logit\{P\{Y = 1|G = g, E = e\}\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 e g.
\]

If the outcome is rare, then odds ratios approximate risk ratios and RERI is given approximately by

\[RERI = e^{\gamma_1 + \gamma_3} - 1\]

\[RR_{01} = e^{\gamma_1}\]

and \( RR_{00} = e^{\gamma_3} \). We can thus still estimate all the components of the proportions attributable to interaction using the estimates from the logistic regression in (2) and could compute these proportions by:

\[
pAI_{G=0}(E) = \frac{(e^{\gamma_1 + \gamma_3} - 1)P(G = 1)}{(e^{\gamma_1} - 1) + (e^{\gamma_1 + \gamma_3} - 1)P(G = 1)}
\]

\[
pAI_{E=0}(G) = \frac{(e^{\gamma_1 + \gamma_3} - 1)P(E = 1)}{(e^{\gamma_3} - 1) + (e^{\gamma_1 + \gamma_3} - 1)P(E = 1)}
\]

As discussed in the Appendix, these same expressions can be used even when control is made for covariates in the logistic regression. This approach also works when using logistic regression in a case-control study. If the outcome is rare or incidence density sampling is used, then we can estimate the various components in the decomposition by

\[
RR_{01} = e^{\gamma_1}, RR_{00} = e^{\gamma_3}, RERI = e^{\gamma_1 + \gamma_3} - e^{\gamma_1} - e^{\gamma_3} + 1
\]

and in addition, \( P(G = 1) \) and \( P(E = 1) \) can be estimated approximately in a case-control study using the probability of \( G \) and \( E \), respectively, among the controls. Thus, we can proceed with estimating the components of the decomposition, even in a case-control study.

Standard errors for these various expressions, using the delta method, along with SAS and Stata code to estimate proportions attributable to interaction and their standard errors, using logistic regression, are given in the eAppendix (http://links.lww.com/EDE/A783). If the sample size is relatively small, it may be preferable to use bootstrapping to obtain standard errors. A similar approach can also be used if control is made for some set of covariates \( C \) or if one or both the exposures are continuous rather than binary; see eAppendix (http://links.lww.com/EDE/A783) for details.

One of the motivations often given for studying interactions, specifically on the additive scale, is to identify which subgroups would benefit most from intervention when resources are limited.1-3 In settings in which it is not possible to intervene directly on the primary exposure of interest, one might instead be interested in which other covariates could be intervened upon to eliminate much or most of the effect of the primary exposure of interest. The methods described here for attributing effects to interactions can be useful in assessing this and identifying the most relevant covariates for intervention.

RELAXING THE INDEPENDENCE ASSUMPTION

Our discussion up until now has assumed that the distributions of the 2 exposures are statistically independent in the population. This assumption may not always be plausible. If \( G \) and \( E \) represent genetic and environmental exposures, then the assumption of independence in the population is often not unreasonable, although there are documented cases1,3 in which genetic variants for an outcome do affect environmental exposures for the same outcome and so the assumption has to be assessed on
a case-by-case basis. When the exposures are 2 environmental factors, or 2 behavioral factors, the 2 exposures may often be correlated with each other. In this section, we will consider what can be concluded when the 2 exposures are instead correlated.

We will assume here that the ordering of the 2 exposures is known (eg, that \( G \) precedes \( E \)). In this setting, even if \( G \) affects \( E \), the decompositions we considered in the previous sections will still apply for the second exposure, ie, for \( E \), provided the effect of \( E \) on \( Y \) is unconfounded conditional on \( G \) (and conditional on, if applicable, measured covariates \( C \). Under this assumption of no confounding for \( E \), we will still have that the total effect of \( E \) decomposes into the sum
\[
(p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)
\]
on the absolute risk scale, and we can use the sum of these 2 components as our estimate of the total effect. Likewise, the regression decomposition method in the previous section will still be applicable and
\[
(p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)
\]
would constitute the proportion of the effect attributable to interaction. And similarly on the ratio scale,
\[
\frac{(RERI)P(G = 1)}{(RR_{01} - 1) + (RERI)P(G = 1)}
\]
would still constitute the proportion of the effect attributable to interaction. The methods in the previous 2 sections still apply even if \( G \) affects \( E \) or if \( G \) and \( E \) are otherwise correlated.

However, the decomposition of a total effect into a conditional effect and an interaction considered in previous sections does not apply directly for the first exposure \( G \), when \( G \) affects \( E \). Intuitively, this is because the effect of \( G \) on \( Y \) does not depend only on the presence or absence of \( E \) but it is also the case that whether \( E \) is itself present (and thus whether the interaction operates) depends on \( G \). Said another way, if \( G \) affects \( E \), \( E \) is not simply an effect modifier for \( G \) but it is also potentially a mediator for \( G \). Our decompositions above are no longer applicable. An alternative decomposition does, however, hold. Specifically, it can be shown (see Appendix) that, when \( G \) affects \( E \), we have the following decomposition for the total effect of \( G \):

\[
(p_{g=1} - p_{g=0}) = (p_{11} - p_{01}) + (p_{10} - p_{00})P(E = 1|G = 1) + (p_{01} - p_{00})(p(E = 1|G = 1) - P(E = 1|G = 0)).
\]

The decomposition of the total effect of \( G \), \( p_{g=1} - p_{g=0} \), now consists of 3 components. We will consider each component in turn. The first component, \( p_{11} - p_{01} \), is simply the effect of \( G \) in the absence of \( E \), ie, the portion of the effect of \( G \) that would remain if \( E \) were fixed to 0. This is analogous to the first component in the 2-way decompositions above. The second component, \( p_{10} - p_{00} \), is the effect attributable to interaction, but now the interaction term, \( p_{11} - p_{10} - p_{01} + p_{00} \), is multiplied by \( P(E = 1|G = 1) \) when \( G \) affects \( E \) rather than being multiplied by \( P(E = 1) \), as when \( G \) and \( E \) were independent; note that when \( G \) and \( E \) are independent, \( P(E = 1|G = 1) \) reduces to \( P(E = 1) \). The third component, \( p_{01} - p_{00} \), is absent from the 2-way decomposition; it is essentially the main effect of \( E \) in the absence of \( G \), \( p_{01} - p_{00} \), multiplied by the effect of \( E \) on \( E \), \( P(E = 1|G = 1) - P(E = 1|G = 0) \); it could be interpreted as a mediated main effect; note again when \( G \) and \( E \) are independent \( P(E = 1|G = 1) - P(E = 1|G = 0) \) = 0 and thus this third component vanishes.

In the Appendix, we further discuss the relationship between this decomposition and the decompositions in the mediation analysis literature.

Thus, when \( G \) affects \( E \), and we are decomposing the total effect of \( G \), 2 things happen to the decomposition we had under independence. First, because \( G \) affects \( E \), we need to take into account that the presence of \( E \) (and thus the possibility that the interaction between the 2 operates) is itself affected by \( G \) and thus the interaction term in the second component is multiplied by \( P(E = 1|G = 1) \) rather than \( P(E = 1) \). Second, when \( G \) affects \( E \), a change in \( G \) from 0 to 1 will also change \( E \), and thus the main effect of \( E \) is more likely to operate, which introduces a third component. \( p_{01} - p_{00} \), \( P(E = 1|G = 1) - P(E = 1|G = 0) \), to the decomposition.

Under this setting of \( G \) affecting \( E \), the proportion of the effect attributable to interaction becomes:

\[
pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1)}{(p_{g=1} - p_{g=0})}.
\]

In this context, we might also wonder what the consequences are of ignoring dependence between \( G \) and \( E \) and proceeding with estimating the proportion attributable to interaction measure when independence of \( G \) and \( E \) is (incorrectly) assumed, ie, of using the measure

\[
pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1)}{(p_{g=1} - p_{g=0})}.
\]

It is shown in the Appendix that if the latter measure is used for the proportion attributable to interaction, incorrectly assuming independence, then although the latter measure does not actually capture the proportion of the effect attributable to interaction, it does nonetheless constitute a lower bound on the proportion of the effect of \( G \) that would be eliminated by fixing \( E \) to 0, provided \( G \) has a non-negative effect on \( E \) and \( E \) has a non-negative effect on \( Y \) (at least in the absence of \( G \). Thus, even if one proceeds with the more naive estimate of the proportion attributable to interaction, ignoring (incorrectly) the dependence between \( G \) and \( E \), one still, under fairly reasonable assumptions, obtains a lower bound on the proportion of the effect of \( G \) eliminated by fixing \( E \) to 0.

Further extensions to this approach of relaxing the assumption of independence are discussed in the Appendix. There this is generalized to nonbinary exposures and outcomes, to the ratio scale, and to settings in which covariates are needed to control for confounding.
When \( G \) affects \( E \), 2 other alternative approaches are worth noting. First, instead of decomposing the total effect into a component due to interaction and the various main effects, one might alternatively use methods for mediation. If \( G \) affects \( E \) and \( E \) affects \( Y \), then \( E \) will in general be a mediator for the effect of \( G \) on \( Y \), and one can assess how much of the effect of \( G \) on \( Y \) is mediated by \( E \). Methods for mediation and easy-to-use software packages\(^6\) are now available to carry out such mediation analysis. These methods now also allow for interactions between the 2 exposures \( G \) and \( E \).\(^7\) Because these methods are described elsewhere, we will not consider them in detail here. It should be noted, however, that these methods address different questions than the ones we have been considering in this article. However, when \( G \) affects the second exposure \( E \), the questions concerning mediation may be the more relevant questions of interest. One can use these methods to assess the proportions between the 2 exposures \( G \) and \( E \), and one can assess how much of the effect of \( G \) on \( Y \) mediated through \( E \).

This proportion-mediated measure is related to, but not identical with, the proportion eliminated discussed above.\(^9\) The proportion eliminated is not always identical to the proportion mediated because it considers what would happen if we fix the second exposure (the mediator \( E \)) to a particular level (rather than allowing \( G \) to affect it) (see Robins and Greenland\(^6\) and VanderWeele\(^9\) for further discussion). The decomposition above also gives an interpretation to the portion-eliminated measure: it states that the difference between the total effect and the portion of the effect that would remain if \( E \) were fixed to zero is equal to the sum of the interaction term and the mediated main effect (ie, the second and third terms in the decomposition above). Second, yet another approach to assess the importance of interaction with regard to \( G \) when \( G \) affects \( E \) is to decompose not a total effect of \( G \) on \( Y \) but rather to focus on the joint effects of \( G \) and \( E \) together and to decompose this joint effect. This is the approach we consider in the following section.

**DECOMPOSITION OF JOINT EFFECTS INTO MAIN EFFECTS AND AN INTERACTIVE COMPONENT**

Another decomposition would be to decompose the joint effects of the 2 exposures, \( G \) and \( E \), into 3 components, the effect due to \( G \) alone, due to \( E \) alone, and due to their interaction. On the risk difference scale, this is

\[
\frac{p_{11} - p_{00}}{p_{10} - p_{00}} + \frac{p_{01} - p_{00}}{p_{10} - p_{00}} + \frac{p_{10} - p_{00}}{p_{10} - p_{00}}.
\]

We could then also compute the proportion of the effect due to \( G \) alone, due to \( E \) alone, and due to their interaction, and carry out a decomposition like this even if \( G \) affects \( E \).

On the risk ratio scale, we can decompose the excess relative risk for both exposures \( RR_{11} - 1 \) into the excess relative risk for \( G \) alone, \( E \) alone, and their interaction, \( RERI \). Specifically we have

\[
RR_{11} - 1 = (RR_{00} - 1) + (RR_{01} - 1) + RERI.
\]

We could then likewise compute the proportion of the effect due to \( G \) alone, due to \( E \) alone, and due to their interaction, and the joint effect attributable to \( G \) alone, to \( E \) alone, and to their interaction are given approximately by:

\[
\begin{align*}
RR_{00} - 1 &= e^{\gamma_{1} + \gamma_{3} + \gamma_{4} - 1} \\
RR_{11} - 1 &= e^{\gamma_{1} + \gamma_{3} + \gamma_{4} - 1} \\
RR_{01} - 1 &= e^{\gamma_{3} + \gamma_{4} - 1} \\
RR_{10} - 1 &= e^{\gamma_{1} + \gamma_{2} + \gamma_{4} - 1} \\
RERI &= (e^{\gamma_{1} + \gamma_{2} + \gamma_{3} + \gamma_{4} - 1} - e^{-1} - e^{-2} + 1)/e^{\gamma_{1} + \gamma_{2} + \gamma_{3} - 1}.
\end{align*}
\]

As discussed in the Appendix, these same expressions can be used even when control is made for covariates in the logistic regression. In the eAppendix (http://links.lww.com/EDE/A783), we give standard errors for these proportion measures as well as SAS and Stata code to estimate the proportions and their standard errors and 95% confidence intervals.

Rothman\(^3\) considered a measure of interaction that he called the attributable proportion, defined as \( \frac{RERI}{RR_{11} - 1} \); the denominator Rothman used was \( RR_{11} - 1 \). The measure was meant to capture the proportion of the disease in the doubly exposed group that is due to the interaction. Rothman\(^3\) also considered an alternative measure, \( \frac{RERI}{RR_{11} - 1} \), which captured the proportion of the effect of both exposures on the additive scale that is due to interaction. Most of the subsequent literature has focused on the former measure and likewise most of the other literature on attributable fractions focuses on the proportion of disease attributable to an exposure\(^2\) or to an interaction. However, using the latter measure, ie, using \( \frac{RERI}{RR_{11} - 1} \), as the denominator, and focusing on the proportion of the effect due to interaction in fact has a number of advantages: both the numerator and the denominator are then on the additive excess relative risk scale; when the entirety of the effect is due to the interaction, the latter measure is then 100% and not some number less than 100%; and the latter measure is moreover invariant to recoding of the outcome.\(^1\) Furthermore,
as we have shown here, the latter measure is what is involved in the decomposition above. With Rothman’s primary $\frac{RERI}{RR_{11}-1}$ even if all the joint effect were due to interaction so that the effect $G$ alone and $E$ alone were both risk ratios of 1, ie, $RR_{10} = 1$ and $RR_{01} = 1$, we would nevertheless have that Rothman’s primary attributable proportion measure would be $\frac{RERI}{RR_{11}-1} = \frac{RR_{11} - RR_{00} + 1}{RR_{11}-1} = \frac{RR_{11} - 1 - 1 + 1}{RR_{11}-1} = \frac{RR_{11} - 1}{RR_{11}-1} < 1$, ie, even if the entirety of the joint effect of both exposures were due to interaction, the attributable proportion measure is still less than 100%. The measure $\frac{RERI}{RR_{11}-1}$ does not have this issue.

It is 100% when the main effects of $G$ alone and $E$ alone were both risk ratios of 1; ie, when the entirety of the joint effect is due to interaction. The measure $\frac{RERI}{RR_{11}-1}$ captures the proportion of the joint effect attributable to interaction.

The attributable proportion of joint effects measure, $\frac{RERI}{RR_{11}-1}$, is also attractive from another standpoint. Skrondal criticized Rothman’s original attributable proportion measure because, in the presence of covariates, if the risks follow a linear risk model that is additive in the covariates, $P(Y = 1 | G = g, E = e, C = c) = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 ge + \alpha_4 c$, then, although the additive interaction, $P_{11} - P_{10} - P_{01} + P_{00} = \alpha_3$, does not vary across strata of the covariates, Rothman’s primary attributable proportion measure, $\frac{RERI}{RR_{11}} = \frac{\alpha_3}{\alpha_0 + \alpha_1 + \alpha_2 + \alpha_3 + \alpha_4}$, does vary across strata of the covariates. One may or may not think that this is an important criticism of the attributable proportion measure; however, the attributable proportion measure for joint effects, $\frac{RERI}{RR_{11}-1} = \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3}$, does not vary with the covariates and thus circumvents this criticism entirely.

**EMPIRICAL ILLUSTRATION**

We illustrate the various decompositions with an example from genetic epidemiology. We use data from a case-control study of lung cancer at Massachusetts General Hospital (Miller et al13) of 1836 cases and 1452 controls. Eligible cases included any person over the age of 18 years; the controls were recruited from among the friends or spouses of patients with cancer or the friends or spouses of other surgery patients in the same hospital. The study included information on smoking and genotype information on locus 15q25.1. For simplicity in this illustration, we will code the exposure as binary so that smoking is ever versus never and the genetic variant is a comparison of 0 versus 1 or 2 T alleles at rs8034191. See the Appendix and eAppendix (http://links.lww.com/ED/EA783) for approaches handling ordinal and categorical exposures. Covariate data include age (continuous), sex, and educational history (college degree or more, yes/no). Analyses were restricted to white persons. Genetic variants on 15q25.1 have been found to be associated with both smoking and lung cancer,14,15 and thus, we are in a setting in which the first exposure $G$ is correlated with the second exposure $E$. The prevalence of the exposures among the controls (which approximates that of the underlying population since the outcome is rare) is $P(G = 1) = 56.7\%$ and $P(E = 1) = 64.94\%$. When we fit the logistic regression model in (2), adjusting also for covariates, we obtain estimates: $\gamma_1 = 0.04$ (95% CI = 0.33 to 0.41), $\gamma_2 = 1.33$ (1.01 to 1.64), $\gamma_3 = 0.49$ (0.08 to 0.89). The main effect of $G$ is small, the main effect of $E$ is large, and the interaction is of moderate size. If we use the regression coefficients to calculate the proportion attributable to interaction for smoking $E$, we obtain a proportion of 34.5% (7.1% to 61.9%). Even if we eliminated the genetic exposure, 65.5% of the effect of smoking would remain (34.5% would be eliminated).

We could proceed with a similar analysis with $G$ but because $G$ affects $E$ here we need to be somewhat more careful in interpretation. Here, however, the correlation between $G$ and $E$, although present, is quite weak, and so the decomposition assuming independence might not be a bad approximation. If we proceed with the decomposition, we obtain that the proportion of the effect of $G$ due to interaction is 98% (58% to 137%). Almost all the effect of $G$ is due to the presence of $E$ and its interaction with $E$. As discussed above, if we can assume that the variants increase smoking, and that smoking increases lung cancer (both reasonable assumptions here), then 98% (95% CI = 58% to 137%) would be a lower bound on the proportion of the effect of $G$ that would be eliminated if we were to eliminate smoking. And, indeed, there is now strong evidence elsewhere that the genetic variants do not have an effect on lung cancer for nonsmokers.16,17

The results are summarized in the first 2 lines of the Table. If we proceed with the decomposition of the joint effect, then the proportions attributable to $G$ alone, $E$ alone, and to their interaction are:

\[
\begin{align*}
RR_{10} - 1 & = 0.8\% (95\% CI = -6.2\% \text{ to } 7.7\%) \\
RR_{11} - 1 & = 51.4\% (33.4\% \text{ to } 69.4\%) \\
RERI & = 47.8\% (33.3\% \text{ to } 62.3\%)
\end{align*}
\]

The results are summarized in the third line of the Table. Almost none of the joint effect (comparing both $G$ and $E$ present to both absent) is due to the effect of $G$ in the absence of $E$, about 51% is due to $E$ in the absence of $G$, and about 48% is due to the interaction between $G$ and $E$. Note that the decompositions for total effects and for joint effects differ in their denominators and so are not directly comparable to each other: the decomposition for joint effect considers the proportion of the effect due to interaction when comparing both exposures present versus neither present; the decompositions for total effects consider the proportion of the effect due to interaction
when one exposure is present (and the other is fixed at its actual level) versus when that same single exposure is absent.

**DISCUSSION**

In this article, we have considered the decomposition of a total effect into a conditional effect when the other exposure is fixed to 0 and a component due to interaction. This decomposition can be done with both exposures if the 2 exposures are statistically independent in distribution, but can be done only with the second exposure in settings in which the first exposure affects the second. Other decompositions for the first exposure are then possible, but the interpretation becomes somewhat more complicated. Even in this case, the joint effects of both exposures can still be decomposed into the component due to the first exposure alone, due to the second exposure alone, and due to their interaction. In the Appendix, fairly general methods are given using linear regression for carrying out these decompositions with binary, ordinal, or continuous exposures. In the eAppendix (http://links.lww.com/EDE/A783), methods and software are provided for these decompositions using logistic regression and linear regression when the outcome is binary or continuous and the exposures are binary or continuous. These various decompositions can shed light on the proportion of various effects that are attributable to interaction.

Several motivations are commonly given for assessing interaction: first, to identify subgroups for which an intervention on the exposure might be most effective in settings in which resources are limited, second, to assess evidence for mechanistic forms of interaction, third, to leverage interaction to increase power for confounding for the effects of the effect modifier itself. These issues of confounding control are discussed in greater detail in the Appendix. We have assumed throughout, for simplicity, that the effects of both factors are unconfounded, but these assumptions need to be thought about more carefully if these measures are to be used in making policy decisions. However, provided such control for confounding for both factors has been made, the measures considered in this article can be useful in determining how much of an effect could be eliminated by intervening on an effect modifier.

**REFERENCES**

Decomposition of a Total Effect into a Conditional Effect and a Portion Due to Interaction

We will let \( G \) and \( E \) denote 2 exposures of interest which may be binary, continuous, or categorical and let \( Y \) be an outcome of interest that may be binary or continuous. Let \( Y_g \) denote the counterfactual outcome for an individual if \( G \) were set to \( g \), let \( Y_e \) denote the counterfactual outcome for an individual if \( E \) were set to \( e \), and let \( Y_{ge} \) denote the counterfactual outcome for an individual if \( G \) were set to \( g \) and \( E \) were set to \( e \). We will let \( X \perp Y \mid Z \) denote that \( X \) is independent of \( Y \) conditional on \( Z \). We will say that the effect of \( G \) on \( Y \) is unconfounded conditional on \( C \) if \( Y_g \perp G \mid C \). We will say that the effect of \( E \) on \( Y \) is unconfounded conditional on \( C \) if \( Y_e \perp E \mid C \). We will say the joint effects of \( G \) and \( E \) on \( Y \) are unconfounded conditional on \( C \) if \( Y_{ge} \perp (G, E) \mid C \).

Proposition 1. For any 2 levels \( e_1 \) and \( e_0 \) of \( E \) and any level \( g_0 \) of \( G \), we have the decomposition:

\[
\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] = \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \, dP(g | c).
\]

Proof.

We have:

\[
\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] = \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \, dP(g | c).
\]

This completes the proof.

In Proposition 1, we can decompose a total effect, \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \), into an effect conditional on \( G = g_0 \), namely \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \), and a component which is a summary measure of effect modification \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \, dP(g | c) \).

The proportion attributable to interaction is then defined by

\[
PAI_{G=g_0}(E) = \frac{\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \, dP(g | c)}{\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \, dP(g | c)}.
\]

The decomposition here is given at the counterfactual level and, as noted above, it is a decomposition of a total effect into an effect conditional on \( G \) and a measure of effect modification. Note that this decomposition and the proportion due to interaction will vary for different values of \( G = g_0 \) and thus the reference value \( g_0 \) must be specified. This reference value was taken as \( G = 0 \) in the text; it is the value at which the conditional effect, \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \), is calculated. The decomposition is given for a particular level of the covariates \( C = c \), but we can also marginalize over \( C \) to obtain

\[
\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0] = \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0] + \int\mathbb{E}[Y_{e_1} - Y_{e_0} | g, c] - \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, c] \, dP(g | c).
\]

Note then, however, that the first term in the decomposition \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, c] \) is the effect of \( E \) on \( Y \) conditional on \( G = g_0 \) and marginalized over the distribution \( P(C) \). It will not in general equal \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0] \) since with the decomposition \( \mathbb{E}[Y_{e_1} - Y_{e_0} | g_0, C] \) is marginalized over \( P(C) \) rather than \( P(C | g_0) \).

Under assumptions about confounding, we can identify each component of the decomposition.

Proposition 2. Suppose that the effect of \( E \) on \( Y \) is unconfounded conditional on \( C, G \) then:

\[
\mathbb{E}[Y_{e_1} - Y_{e_0} | g, C] = \mathbb{E}[Y | g, e_1, c] - \mathbb{E}[Y | g, e_0, c]
\]

and we can thus identify the components in Proposition 1 and the right-hand side of the decomposition in Proposition 1 can be written in terms of observed data as:

\[
\mathbb{E}[Y_{e_1} - Y_{e_0} | g_0] = \mathbb{E}[Y | g_0, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] + \int\mathbb{E}[Y | g, e_1, c] - \mathbb{E}[Y | g, e_0, c] \, dP(g | c).
\]
If, moreover, the joint effects of $G$ and $E$ are unconfounded conditional on $C$, then we can write the decomposition as:

$$E[Y_{e=1} - Y_{e=0}] = E[Y_{g=0} - Y_{g=0}] + \int \left( \left[ E[Y_{g} - Y_{g}] - E[Y_{g=g} - Y_{g}^{*}] \right] - E[Y_{g=g} - Y_{g}] ight) dP(g|c)$$

**Proof.** If the effect of $E$ on $Y$ is unconfounded conditional on $(C, G)$, then we have

$$E[Y_{e=1} - Y_{e=0}] = E[Y|g, c] - E[Y|g, e, c]$$

If the joint effects of $G$ and $E$ are unconfounded conditional on $C$, then we have $E[Y|g, c] = E[Y|g]$ and thus:

$$E[Y_{e=1} - Y_{e=0}] = E[Y_{g}=0] - E[Y_{g=g}^{*}]$$

This completes the proof.

If the effect of $E$ on $Y$ is unconfounded conditional on $C$ alone as would be the case under Proposition 2 if $G$ and $E$ were independent conditional $C$, then we would also have $E[Y_{e=1} - Y_{e=0}] = E[Y|C] - E[Y|g, e, c]$. Otherwise, we will not have $E[Y_{e=1} - Y_{e=0}] = E[Y|C] - E[Y|g, c]$, but we could still obtain $E[Y_{e=1} - Y_{e=0}]$ under Proposition 2 using the sum of the 2 components, $E[Y|g, e, c] - E[Y|g, e, c]$ and $E[Y|g, e, c] - E[Y|g, e, c] + E[Y|g, e, c] + E[Y|g, e, c] dP(g|c)$. Note that in the second part of Proposition 2, to obtain the decomposition, $E[Y_{e=1} - Y_{e=0}] = E[Y_{g=0} - Y_{g=g}^{*}]$ and thus:

$$E[Y_{e=1} - Y_{e=0}] = E[Y_{g}=0] - E[Y_{g=g}^{*}]$$

and thus the first component in the empirical decomposition in Proposition 2 is equal to:

$$E[Y|g, e, c] - E[Y|g, e, c] = (\alpha_{e} + g_{0}\alpha_{g})(e_{1} - e_{0})$$

and the second is equal to:

$$E[Y|g, e, c] - E[Y|g, e, c] = (\alpha_{e} + g_{0}\alpha_{g})(e_{1} - e_{0})$$

The proportion due to interaction is then $(\alpha_{e} + g_{0}\alpha_{g})/(\alpha_{e} + g_{0}\alpha_{g})$. When $G$ and $E$ are binary and $g_{0}=0$ and there are no covariates, the 2 components reduce to $\alpha_{e}$ and $\alpha_{g}P(G=1)$ and the proportion due to interaction is $\alpha_{e}P(G=1)$ as the text.

Note, however, that when the exposures are not binary, the measures themselves (and thus the proportion attributable to interaction) may vary depending on the values, $e_{1}$ and $e_{0}$ of $E$ that are being compared and also again on the reference value, $g_{0}$ of $G$.

On the risk ratio scale, we let $RR_{ge} = \frac{P(Y|g=1)}{P(Y|g=0)}$ and $RR_{ce} = \frac{P(e=1)}{P(e=0)}$ and $RR_{ge} = \frac{P(Y=g|e=1)}{P(Y=g|e=0)}$. The decomposition (p_{e=1} - p_{e=0}) = (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G=1) when divided by $p_{e=0}$ is

$$RR_{e=1} = \kappa(\RR_{g=1} - \RR_{g=0}) + \kappa(\RR_{g=1} - \RR_{g=0} - \RR_{g=0} + \RR_{g=0})P(G=1)$$

where $\kappa$ is a scaling factor given by $\kappa = P_{e=0}/P_{e=0}$. The proportion of the effect of $E$ attributable to interaction is given by:

$$pAI_{G=e|E}(E) = \frac{(\RR_{g=1} - \RR_{g=0} - \RR_{g=0} + \RR_{g=0})P(G=1)}{(\RR_{g=1} - \RR_{g=0} - \RR_{g=0} + \RR_{g=0})P(G=1)}$$

As noted in the text, if we use the logistic regression model

$$\logit\{P(Y=1|G=g, E=e, C=c)\}$$

$$\gamma_{0} + \gamma_{1}g + \gamma_{2}e + \gamma_{3}eg + \gamma_{4}c.$$
then proportion attributable to interaction if the exposures are binary can be approximated by

\[ pAI_{G \rightarrow E}(E) = \frac{e^{g1}e^{g2}e^{g3}e^{g4} - e^{g1}e^{g2} + 1}{(e^{g1}+e^{g2})^2} P(G = 1) \]

In the eAppendix (http://links.lww.com/EDE/A783), we discuss estimating standard errors for this proportion attributable to interaction.

**Analogous Results for G**

Note that, by symmetry, from Proposition 1, we have the decomposition

\[
\mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] = \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c, e] + \int \left[ \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | e, c] - \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | e, c] \right] dP(e | c).
\]

This decomposition applies even if \( G \) affects \( E \). If \( G \) and \( E \) were independent so that \( G \) did not affect \( E \), then we would have an analog of Proposition 2, which would be that if the effect of \( G \) on \( Y \) is unconfounded conditional on \( (C, E) \) then we have \( \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] = \mathbb{E}[Y_{a_{1}} | c, e] = \mathbb{E}[Y_{b_{0}} | c, e] \) and under independence also, \( \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] = \mathbb{E}[Y_{a_{1}} | c, e] = \mathbb{E}[Y_{b_{0}} | c, e] \), and we can thus write the decomposition of the total effect of \( G \) in terms of observed data as:

\[
\mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] = \mathbb{E}[Y_{a_{1}} | c, e] = \mathbb{E}[Y_{b_{0}} | c, e] + \int \left[ \mathbb{E}[Y_{a_{1}} | c, e] - \mathbb{E}[Y_{b_{0}} | c, e] \right] dP(e | c).
\]

If, moreover, the joint effects of \( G \) and \( E \) are unconfounded conditional on \( C \), then we can write the decompositions as:

\[
\mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] = \mathbb{E}[Y_{a_{1}} | c, e] = \mathbb{E}[Y_{b_{0}} | c, e] + \int \left[ \mathbb{E}[Y_{a_{1}} | c, e] - \mathbb{E}[Y_{b_{0}} | c, e] \right] dP(e | c).
\]

**Settings in Which \( G \) Affects \( E \)**

If \( G \) affects \( E \), then Proposition 2 for \( E \) still applies. We can still thus empirically decompose the total effect of \( E \) on \( Y \) into a conditional effect and the portion due to control for \( G \) will in general be needed to control for confounding for \( E \). But we can still obtain \( \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | k] \), even if \( G \) affects \( E \) under Proposition 2, using the sum of the 2 components, \( \mathbb{E}[Y_{a_{1}} | c, e] = \mathbb{E}[Y_{b_{0}} | e, c] \) and

\[
\mathbb{E}[Y_{a_{1}} | c, e] - \mathbb{E}[Y_{b_{0}} | e, c] = \int \left[ \mathbb{E}[Y_{a_{1}} | c, e] - \mathbb{E}[Y_{b_{0}} | e, c] \right] dP(e | c).
\]

However, if \( G \) affects \( E \), then the analog of Proposition 2 for \( G \) will not apply. We still have the analogous decomposition to that in Proposition 1:

\[
\mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | k] = \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | 0, c] + \int \left[ \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | k, c] - \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | 0, c] \right] dP(e | c).
\]

However, the counterfactuals of the form \( \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | 0, c] \) will not be identified and so we cannot empirically estimate the various parts of the decomposition. This is because when \( G \) affects \( E \), the analog of Proposition 2 for \( G \) would require that the effect of \( G \) on \( Y \) is unconfounded conditional on \( (C, E) \) and this fails because \( G \) itself affects \( E \).

However, when \( G \) affects \( E \), we still have the decomposition in the Proposition below.

**Proposition 3.** If the effect of \( G \) on \( Y \) is unconfounded conditional on \( C \), and the effects of \( G \) and \( E \) are unconfounded conditional on \( C \) then we have

\[
\mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | k] = \mathbb{E}[Y_{a_{1}} | 0, c] = \mathbb{E}[Y_{b_{0}} | 0, c],
\]

\[
+ \int \left[ \mathbb{E}[Y_{a_{1}} | e, c] - \mathbb{E}[Y_{b_{0}} | e, c] \right] dP(e | c).
\]

**Proof.** We have that \( \mathbb{E}[Y_{a_{1}} - Y_{b_{0}} | c] \)

\[
= \mathbb{E}[Y_{a_{1}} | c, e] - \mathbb{E}[Y_{b_{0}} | c, e]
\]

\[
= \mathbb{E}[Y_{a_{1}} | 0, c] - \mathbb{E}[Y_{b_{0}} | 0, c] + \int \left[ \mathbb{E}[Y_{a_{1}} | e, c] - \mathbb{E}[Y_{b_{0}} | e, c] \right] dP(e | c).
\]

In the decomposition above, the first term, 
\[ \mathbb{E}[Y_{Z_0} - Y_{Z_0}] = [\mathbb{E}[Y | g_1, e_0, c] - \mathbb{E}[Y | g_0, e_0, c]] \]

is the controlled direct effect of \( G \), comparing levels, \( g_1 \) and \( g_0 \), when \( E \) is fixed to \( e_0 \). The second term, 
\[ \int [\mathbb{E}[Y_{Z_0} - Y_{Z_0}] | c] - \mathbb{E}[Y_{Z_0} - Y_{Z_0}] | c] dP(e | g_1, c), \]

is the portion attributable to interaction; it is an interaction, 
\[ \mathbb{E}[Y_{Z_0} - Y_{Z_0}] | c] - \mathbb{E}[Y_{Z_0} - Y_{Z_0}] | c], \]

standardized by the distribution, \( P(e | g_1, c) \), the third and final term, 
\[ \int [\mathbb{E}[Y_{Z_0} - Y_{Z_0}] | c] dP(e | g_1, c) - dP(e | g_0, c)), \]

is the main effect of \( E \) when \( G = g_0 \), standardized by \( P(e | g_1, c) \) versus \( P(e | g_0, c) \), which provided the effect of \( G \) on \( E \) is unconfounded conditional on \( C \), is essentially the effect of \( G \) on \( E \) and thus the third term is in some sense a mediated main effect.

When \( G, E \), and \( Y \) are binary and \( g_0 = 0 \) is selected as the reference level, and no covariates are required for confounding, the decomposition reduces to: 
\[ \mathbb{E}[Y | G] = \mathbb{E}[Y | G = 1] + \mathbb{E}[Y | G = 0]P(E = 1 | G = 1) + \mathbb{E}[Y | G = 0]P(E = 1 | G = 0) \]

Or, expressed in terms of the observed data, as \( (P_{g=1} - P_{g=0}) \)
\[ = (P_{01} - P_{00}) + (P_{10} - P_{01} + P_{00})P(E = 1 | G = 1) + (P_{01} - P_{00})P(E = 1 | G = 1) - P(E = 1 | G = 0) \]

as in the text. The proportion attributable to interaction is then:
\[ pAI_{E=0}(G) = \frac{(P_{10} - P_{01} + P_{00})P(E = 1 | G = 1)}{(P_{g=1} - P_{g=0})}. \]

Note that when \( G \) has a non-negative effect on \( E \), and \( E \) has a non-negative effect on \( Y \) (in the absence of \( G \)), then \( P(E = 1 | G = 1) = P(E = 1 | G = 0) \geq 0 \) and thus \( P(E = 1 | G = 1) = P(E = 1 | G = 0) \geq 0 \) and \( P(E = 1 | G = 1) = P(E = 1 | G = 0) \geq 0 \) and we then have that \( (P_{10} - P_{01} + P_{00})P(E = 1 | G = 1) \leq (P_{10} - P_{01} + P_{00})P(E = 1 | G = 0) \leq (P_{10} - P_{01} + P_{00})P(E = 1 | G = 0) \) and from this it follows that if the dependence between \( G \) and \( E \) is incorrectly ignored and
\[ \frac{(P_{10} - P_{01} + P_{00})P(E = 1 | G = 1)}{(P_{g=1} - P_{g=0})}. \]
is used for the proportion attributable to interaction, then although the latter measure does not actually capture the proportion of the effect attributable to interaction, it does nonetheless constitute a lower bound on the proportion of the effect of \( G \) that would be eliminated by fixing \( E \) to 0, as indicated in the text. Thus, even if one proceeds with the more naive estimate of the proportion attributable to interaction, ignoring (incorrectly) the dependence between \( G \) and \( E \), one still, under fairly reasonable assumptions, obtains a lower bound on the proportion of the effect of \( G \) eliminated by fixing \( E \) to 0.

The decomposition in Proposition 3 with binary exposures when the effect of \( G \) on \( Y \) and on \( E \) are unconfounded, and the effects of \( (G, E) \) on \( Y \) are unconfounded can be rewritten as:
\[ \mathbb{E}[Y | Y_0] = \mathbb{E}[Y_{10} - Y_{00}] + \mathbb{E}[Y_{01} - Y_{10} - Y_{00}]P(E = 1 | G = 1) + \mathbb{E}[Y_{01} - Y_{00}]P(E = 1 | G = 1) - (P(E = 1 | G = 0)) \]

where \( E \) is the counterfactual outcome for \( E \) fixing \( G \) to \( g \). The analog on the individual counterfactual level is \( Y_1 - Y_0 = (Y_{10} - Y_{00}) + (Y_{11} - Y_{10} - Y_{00})P(E = 1 | G = 1) + (Y_{11} - Y_{00})(E_{g=1} - E_{g=0}) \). These will be decompositions of a total effect. These differ somewhat from the decompositions in the mediation analysis literature. In the mediation analysis literature, the total effect is decomposed into 2 components, what is called a natural indirect effect and a natural direct effect given, respectively, by \( \mathbb{E}[Y_{10} - Y_{00}] \) and \( \mathbb{E}[Y_{10} - Y_{00}] \) or into 3 components, a so-called pure indirect effect, a pure direct effect (equivalent to the natural direct effect just given), and a mediated interaction, which, when identified can be written as \( \mathbb{E}[Y_{10} - Y_{00}] \), \( \mathbb{E}[Y_{01} - Y_{00}] \), and \( \mathbb{E}[Y_{11} - Y_{01} - Y_{10} + Y_{00}]P(E = 1 | G = 1) - (P(E = 1 | G = 0)) \); respectively. In contrast, for the decomposition given in Proposition 3, the “direct effect” given in this decomposition is a controlled direct effect, \( \mathbb{E}[Y_{10} - Y_{00}] \) not a natural direct effect; and the interaction term, \( \mathbb{E}[Y_{11} - Y_{01} - Y_{10} + Y_{00}]P(E = 1 | G = 1) \), is the proportion of the effect attributable to interaction. Note also that if \( G \) does not affect \( E \) (ie, if there is no mediation) then the mediation decomposition into 3 components reduces to a single component (the pure direct effect). However, if \( G \) does not affect \( E \), then, with the decompositions considered in this article, there are still 2 components: the controlled direct effect for \( G \) and also the interaction term.

For the ratio scale, the decomposition, \( (P_{g=1} - P_{g=0}) \)
\[ = (P_{10} - P_{01} + P_{00})P(E = 1 | G = 1) + (P_{01} - P_{00})P(E = 1 | G = 0) \]

is divided by \( p_{g=0} \) is
\[ k = \frac{(R_{g=1} - 1)}{(R_{g=0} - k)} \]
\[ + k(R_{g=1} - R_{g=0} - R_{g=0} + 1)P(E = 1 | G = 1) \]
\[ + k(R_{g=1})P(E = 1 | G = 1) - P(E = 1 | G = 0) \]

where \( k \) is a scaling factor given by \( k = \frac{P_{00}}{P_{g=0}} \). The proportion of the effect of \( G \) attributable to interaction is:
\[ pAI_{E=0}(G) = \frac{(R_{g=1} - R_{g=0} - R_{g=0} + 1)P(E = 1 | G = 1)}{[R_{g=1} + (R_{g=1} - R_{g=0} - R_{g=0} + 1)P(E = 1 | G = 1) + (R_{g=1})P(E = 1 | G = 0)]}. \]

**Decomposition of Joint Effects**

At the counterfactual level, we can decompose the joint effects of the 2 exposures, \( G \) and \( E \), into the effect due to \( G \) alone, the effect due to \( E \) alone and their interaction. We
have
\[ \mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] = \mathbb{E}[Y | g_1, e_0, c] + \mathbb{E}[Y | g_0, e_1, c] - \mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_0, c]. \]

If the joint effects of \( G \) and \( E \) are unconfounded conditional on \( C \), each of these components is identified from the observed data and the decomposition can be rewritten as:

\[
\mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] = \{ \mathbb{E}[Y | g_1, e_0, c] - \mathbb{E}[Y | g_0, e_0, c] \} \\
+ \{ \mathbb{E}[Y | g_0, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] \} \\
+ \{ \mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_1, c] \} \\
- \mathbb{E}[Y | g_0, e_1, c] + \mathbb{E}[Y | g_0, e_0, c].
\]

We can then also compute the proportion of the joint effect due to \( G \) alone as
\[ \frac{\mathbb{E}[Y | g_1, e_0, c] - \mathbb{E}[Y | g_0, e_0, c]}{\mathbb{E}[Y | g_0, e_0, c]} \]
due to \( E \) alone as
\[ \frac{\mathbb{E}[Y | g_0, e_1, c] - \mathbb{E}[Y | g_0, e_0, c]}{\mathbb{E}[Y | g_0, e_0, c]} \]
and due to their interaction as
\[ \frac{\mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] + \mathbb{E}[Y | g_0, e_0, c]}{\mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_0, c]}. \]

Dividing the first decomposition above by \( \mathbb{E}[Y | g_0, e_0, c] \), or the second by \( \mathbb{E}[Y | g_0, e_0, c] \), or both the numerator and the denominator of the proportions by \( \mathbb{E}[Y | g_0, e_0, c] \) yields decompositions and proportions on the ratio scale. All these decompositions are applicable even if \( G \) affects \( E \). On a difference scale, under the linear model
\[ \mathbb{E}[Y | g, E = e, C = c] = \alpha_0 + \alpha_g g + \alpha_e e + \alpha_{ge} eg, \]
we have that the 3 components are given by:

\[
\{ \mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_0, e_0, c] \} = (\alpha_1 + \alpha_{ge} e_0)(g_1 - g_0) \\
\{ \mathbb{E}[Y | g_1, e_0, c] - \mathbb{E}[Y | g_0, e_0, c] \} = (\alpha_2 + \alpha_{ge} g_1)(e_1 - e_0) \\
\{ \mathbb{E}[Y | g_1, e_1, c] - \mathbb{E}[Y | g_1, e_0, c] - \mathbb{E}[Y | g_0, e_1, c] \} \\
+ \mathbb{E}[Y | g_0, e_0, c] = \alpha_3 (g_1 e_1 - g_1 e_0 - g_0 e_1 + g_0 e_0). \]

When \( G \) and \( E \) are binary, these 3 components reduce to \( \alpha_1, \alpha_2, \) and \( \alpha_3 \), respectively. Note, however, that when the exposures are not binary, the measures themselves (and thus the proportion attributable to each component) may vary depending on the values, \( e_1 \) and \( e_0 \), of \( E \) and the values, \( g_1 \) and \( g_0 \), of \( G \) that are being compared.

On a ratio scale, under the logistic regression model with a rare outcome,
\[ \text{logit}\{P(Y = 1 | G = g, E = e, C = c)\} = \gamma_0 + \gamma_g g + \gamma_e e + \gamma_{ge} eg + \gamma_{c} c \]
if \( G \) and \( E \) are binary then the proportions discussed in the text of the joint effect attributable to \( G \) alone, \( E \) alone, and to their interaction are given approximately by:

\[
\frac{RR_{g0}}{RR_{g1}} = \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_{ge} e_0} - 1} \\
\frac{RR_{e0}}{RR_{e1}} = \frac{e^{\gamma_2} - 1}{e^{\gamma_1 + \gamma_{ge} g_1} - 1} \\
RERI = \frac{(e^{\gamma_1 + \gamma_{ge} e_0} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_{ge} g_1} - 1}, \]
respectively. See the eAppendix (http://links.lww.com/EDE/A783) for standard errors.
Relative risk for the numerator and the denominator by the conditional proportion attributable to interaction in stratum $C = c$.

The (marginal) proportion attributable to interaction averaged over covariates can be shown to be:

$$P_{AI_{G=0}}(E) \approx \frac{(e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}{(e^{2} - 1) + (e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}.$$ 

The conditional proportion attributable to interaction in stratum $C = c$ would replace $P(G = 1)$ in both the numerator and the denominator by $P(G = 1|C = c)$.

For the standard error for the proportion due to interaction we will assume that the proportion $P(G = 1)$ is known. Alternatively, the standard errors derived can be interpreted as standard errors for the estimate of the proportion attributable to interaction in a population which had the same underlying risk ratios as the sample in question, but had a prevalence of $G$ equal to the prevalence of $G$ in the sample.

Let

$$V = \begin{pmatrix}
    v_{00} & v_{01} & v_{02} & v_{03} \\
    v_{10} & v_{11} & v_{12} & v_{13} \\
    v_{20} & v_{21} & v_{22} & v_{23} \\
    v_{30} & v_{31} & v_{32} & v_{33}
\end{pmatrix}$$

be the covariance matrix for the estimators $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ of $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'$. By the delta method the variance of our estimator $\hat{Q}$ of $Q = \frac{(e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}{(e^{2} - 1) + (e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'$ is given by:

$$Var(\hat{Q}) = \left(\frac{\partial Q}{\partial (\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}\right)' V \left(\frac{\partial Q}{\partial (\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}\right).$$

We have that

$$\frac{\partial Q}{\partial (\gamma_0, \gamma_1, \gamma_2, \gamma_3)'} = \begin{pmatrix}
    0 \\
    0 \\
    0 \\
    0
\end{pmatrix}$$

as

$$\begin{pmatrix}
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1)
\end{pmatrix}.$$

$$\begin{pmatrix}
    0 \\
    0 \\
    0 \\
    0
\end{pmatrix}$$

as

$$\begin{pmatrix}
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1) \\
    [e^{\gamma_2} - 1] + [e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1]P(B = 1)
\end{pmatrix}.$$

1
Let $K_1$, $K_2$ and $K_3$ denote the first, second, and third non-zero expressions in this vector. We then have

$$\text{Var}(Q) = \frac{\partial Q}{\partial (\gamma_0, \gamma_1, \gamma_2, \gamma_3)^T}' V \frac{\partial Q}{\partial (\gamma_0, \gamma_1, \gamma_2, \gamma_3)^T} = \begin{pmatrix} 0 & v_{00} & v_{01} & v_{02} & v_{03} \\ K_1 & 0 & v_{10} & v_{11} & v_{12} \\ K_2 & v_{20} & v_{21} & v_{22} & v_{23} \\ K_3 & v_{30} & v_{31} & v_{32} & v_{33} \end{pmatrix} \begin{pmatrix} 0 \\ K_1 \\ K_2 \\ K_3 \end{pmatrix}.$$

$$= v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3.$$

### 1.2 Standard Error for the Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

For the three-way decomposition of the joint excess relative risk of both exposures, $RR_{11} - 1$, we have a decomposition into an excess risk relative risk for $G$ alone, an excess relative risk for $E$ alone, and the excess relative risk due to interaction i.e. we have the decomposition: $RR_{11} - 1 = (RR_{10} - 1) + (RR_{01} - 1) + \text{RERI}$. And we can compute the proportion of the joint effect due to $G$ alone $RR_{01} - 1$, and due to $E$ alone $RR_{10} - 1$, and due to their interaction $\frac{\text{RERI}}{RR_{10} - 1}$. Under the logistic regression model with a rare outcome

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1g + \gamma_2e + \gamma_3ge + \gamma_4c,$$

the proportion can be estimated approximately by:

$$RR_{10} - 1 \approx \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1},$$
$$RR_{11} - 1 \approx \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1},$$
$$RR_{01} - 1 \approx \frac{e^{\gamma_2} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1},$$
$$\text{RERI} \approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}.$$

We will now compute the standard errors for these expressions.

For the proportion of the joint effect due to a single exposure alone, we have, by the delta method, that the variance of our estimator $Q$ of $Q = \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ in this expression with $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)^T$ is given by:

$$\text{Var}(Q) = \frac{\partial Q}{\partial (\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)^T}' V \frac{\partial Q}{\partial (\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)^T}.$$

We have that $\frac{\partial Q}{\partial (\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)^T} = \begin{pmatrix} 0 \\ \frac{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \end{pmatrix}.$$

We can then substitute this into the variance formula to get the standard error for each component.
Let $K_1$, $K_2$ and $K_3$ denote the first, second, and third non-zero expressions in this vector. We then once again have $\text{Var}(\hat{Q}) = v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3$.

For the standard error for the proportion of a joint effect attributable to interaction we have, by the delta method, that the variance of the estimator $\hat{Q}$ of $Q = \frac{\langle e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} \rangle}{e^{\gamma_0} + e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3}}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ in this expression with $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ is given by:

$$\text{Var}(\hat{Q}) = \left(\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)}\right)' V \left(\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)}\right).$$

We have that $\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)} = 0$,

$$\left(\begin{array}{c}
\frac{\partial Q}{\partial \gamma_0} \\
\frac{\partial Q}{\partial \gamma_1} \\
\frac{\partial Q}{\partial \gamma_2} \\
\frac{\partial Q}{\partial \gamma_3}
\end{array}\right) = \left(\begin{array}{c}
0 \\
\frac{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_1}}{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_1}} \\
\frac{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_2}}{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_2}} \\
\frac{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_3}}{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - e^{\gamma_3}} \\
\frac{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - 1}{e^{\gamma_1} + e^{\gamma_2} + e^{\gamma_3} - 1}
\end{array}\right).$$

Let $K_1$, $K_2$ and $K_3$ denote the first, second, and third non-zero expressions in this vector. We then have $\text{Var}(\hat{Q}) = v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3$.

1.3. SAS and Stata Code to Implement Proportion of a Total Effect Attributable to Interaction

Suppose we have a SAS dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. To use the code below, the user must input in the third and fourth line of the data step the prevalence of the exposure $G$ ('pg=') and the prevalence of the exposure $E$ ('pg='). In a case-control study, these prevalences should be computed only among the controls. The output will include the proportion of the total effect of $G$ that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to $G$ when $E$ is set to 0. The code will also report the proportion of the total effect of $E$ that is attributed to interaction, along with a 95% confidence interval; once again, the remaining proportion is that attributable to $E$ when $G$ is set to 0.

These measures assume that $G$ and $E$ are independent, and that control has been made for confounding. In this case, the proportion attributable to interaction for $G$ can also be interpreted as the proportion of the total effect of $G$ that would be eliminated if $E$ were set to 0. Likewise, the proportion attributable to interaction for $E$ can also be interpreted as the proportion of the total effect of $E$ that would be eliminated if $G$ were set to 0. When $G$ and $E$ are not independent (e.g. $G$ affects $E$), the measure for the second exposure still carries this interpretation provided control has been made for confounding. However, for the first exposure $G$ the proportion attributable to interaction given in the output corresponds to the proportion of an integrated joint effect due to interaction, as discussed in the Appendix to the paper.

```
proc logistic descending data=mydata outest=myoutput covout;
model y=g e g*e c1 c2 c3;
```
data PAIoutput;
set myoutput;
array mm {*} _numeric_;
pg=0.5;
pe=0.5;
b0=lag4(mm[1]);
b1=lag4(mm[2]);
b2=lag4(mm[3]);
b3=lag4(mm[4]);
v1=lag2(mm[2]);
v2=lag(mm[2]);
v3=mm[2];
v22=lag(mm[3]);
v33=mm[4];
k1=((exp(b2)-1)*(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg) /
((exp(b2)-1)*(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg));
k2=1-
((exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg) /
((exp(b2)-1)*(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg));
k3=((exp(b2)-1)*(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg) /
((exp(b2)-1)*(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg));
vPAIE=v11*k1*k1 + v22*k2*k2 + v33*k3*k3;
PAIE_E=(exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg/(exp(b2)-1)
((exp(b1+b2+b3)-exp(b2)-exp(b1)-1)*pg));
se_PAIE=sqrt(vPAIE);
195_uE=PAIE_E-1.96*se_PAIE;
195_lG=PAIE_E+1.96*se_PAIE;
keep PAI_E ci95_lE ci95_uE PAI_G ci95_lG ci95_uG;
if _n_=5;
run;

proc print data=PAIoutput;
var PAI_E ci95_lE ci95_uE PAI_G ci95_lG ci95_uG;
run;

The equivalent Stata code would be:

```
generate pg=0.5
generate pe=0.5
generate Ige = g*e
logit y g e Ige c1 c2 c3
nlcom (exp(_b[e]+_b[g]+_Ige] - exp(_b[e]) - exp(_b[g])+1)*pe/(exp(_b[g])-1) + (exp(_b[e]+_b[g]+_Ige] - exp(_b[e]) - exp(_b[g])+1)*pe)
```

1.4. SAS and Stata Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction
As discussed in the text it is possible to decompose the joint excess relative risk for both exposures together into three components: (i) a component due to the first exposure $G$ alone, (ii) a component due to $E$ alone, and (iii) a component due to the interaction between the effect of $G$ and $E$. The output gives the proportions due to $G$ alone, the proportion due to $E$ alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other. The code in SAS is:

```
proc logistic descending data=mydata outest=myoutput covout;
   model y=g e g*e c1 c2 c3;
run;

data JOINToutput;
   set myoutput;
   array mm {*} _numeric_;
   b0=lag4(mm[1]);
   b1=lag4(mm[2]);
   b2=lag4(mm[3]);
   b3=lag4(mm[4]);
   v11=lag2(mm[2]);
   v12=lag(mm[2]);
   v13=mm[2];

keep PAG ci95_lG ci95_uG PAE ci95_lE ci95_uE PaINT ci95_lINT ci95_uINT;
if _n_=.S;
run;
```

The equivalent Stata code would be as follows (with the output first giving the proportion of joint effect due to $G$ alone, then due to $E$ alone, and then that due to their interaction):

```
generate Ige = g*e
```
which on the ratio scale can be rewritten as

\[ E \]

Under the logistic regression model with a rare outcome

\[
\text{nlcom } (\exp(_b[g])-1)/(\exp(_b[g]+_b[e]+_b[lgee])-1) \\
\text{nlcom } (\exp(_b[e])-1)/(\exp(_b[e]+_b[g]+_b[lgee])-1) \\
\text{nlcom } (\exp(_b[e]+_b[g]+_b[lgee])-\exp(_b[g]+_b[e]+_b[lgee])-1)/(\exp(_b[g]+_b[e]+_b[lgee])-1)
\]

2. Binary Outcome and Continuous Exposures

2.1. Proportion of a Total Effect Attributable to Interaction

As discussed in the Appendix to the text, for continuous exposures, when the effect of \( E \) on \( Y \) is unconfounded conditional on \((C,G)\) then the total effect of \( E \) on \( Y \), \( E[Y_{e1}|c] - E[Y_{e0}|c] \), could be decomposed into two components as: \( E[Y_{e1}|c] - E[Y_{e0}|c] \)

\[
= E[Y|g_0,e_1,c] - E[Y|g_0,e_0,c] + \int \{ E[Y|g,e_1,c] - E[Y|g,e_0,c] - E[Y|g_0,e_1,c] + E[Y|g_0,e_0,c] \} dP(g|c)
\]

which on the ratio scale can be rewritten as \( E[Y_{e1}|c] - E[Y_{e0}|c] \)

\[
= \kappa \{ E[Y|g_0,e_1,c] \} - 1 + \kappa \int \{ E[Y|g,e_1,c] - E[Y|g,e_0,c] - E[Y|g_0,e_1,c] \} dP(g|c)
\]

where \( \kappa = \frac{E[Y|g_0,e_0,c]}{E[Y|g_0,e_0,c]} \). The proportion of the effect of \( E \) attributable to interaction is given by:

\[
pAI_{G=g_0}(E) = \frac{\int \{ E[Y|g_1,e_1,c] - E[Y|g_1,e_0,c] - E[Y|g_0,e_1,c] \} dP(g|c) \} \{ E[Y|g_0,e_1,c] \} - 1 + \int \{ E[Y|g,e_1,c] - E[Y|g,e_0,c] - E[Y|g_0,e_1,c] \} dP(g|c) + 1 \}
\]

Suppose first that \( E \) is continuous and \( G \) is binary, then this expression reduces to

\[
pAI_{G=g_0}(E) = \frac{\int \{ E[Y|g_1,e_1,c] - E[Y|g_1,e_0,c] - E[Y|g_0,e_1,c] \} dP(G = g_1|c) \} \{ E[Y|g_0,e_1,c] \} - 1 + \int \{ E[Y|g,e_1,c] - E[Y|g,e_0,c] - E[Y|g_0,e_1,c] \} dP(G = g_1|c) + 1 \}
\]

Under the logistic regression model with a rare outcome

\[
\logit\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 e g + \gamma_4 c,
\]

the proportion attributable to interaction is given by approximately by: \( pAI_{G=g_0}(E) \approx \frac{\{e(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1-g_0)e\gamma_3 - e(g_1-g_0)\gamma_1+(g_1-g_0)e\gamma_3 - e(e_1-e_0)\gamma_2+(e_1-e_0)e\gamma_3+1\}P(G = g_1|c) \} \{e(e_1-e_0)\gamma_2+(e_1-e_0)e\gamma_3-1\} + \{e(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1-g_0)e\gamma_3 - e(g_1-g_0)\gamma_1+(g_1-g_0)e\gamma_3 - e(e_1-e_0)\gamma_2+(e_1-e_0)e\gamma_3+1\}P(G = g_1|c) \}
\]

Suppose now that \( G \) is continuous and normally distributed with mean \( E[G|c] = \alpha_0 + \alpha_1 c \)

\[
\alpha_0 + \alpha_1 c
\]
and variance $\sigma^2$. Assuming a rare outcome, under logistic regression (A1) we have:

$$
\int \frac{E[Y|g_0, e_1, c_1]}{E[Y|g_0, e_0, c_0]} dP(g|c) \\
\approx \int \exp\{(-g_0 - g_0)\gamma_1 + (e - e_0)\gamma_2 + (g - g_0e_0)\gamma_3\} dP(g|c) \\
= \exp\{-g_0\gamma_1 + (e - e_0)\gamma_2 - g_0e_0\gamma_3\} \int \exp\{\gamma_1 + e\gamma_3\} dP(g|c) \\
= \exp\{-g_0\gamma_1 + (e - e_0)\gamma_2 - g_0e_0\gamma_3 + (\gamma_1 + e\gamma_3)(\alpha_0 + \alpha_1 c) + \frac{1}{2}(\gamma_1 + e\gamma_3)^2\sigma^2\}
$$

and thus the proportion attributable to interaction is: $pAI_{G=g_0}(E) = \int \left( \frac{E[Y|g_0, e_1, c_1]}{E[Y|g_0, e_0, c_0]} - 1 \right) \frac{E[Y|g_0, e_0, c_0]}{E[Y|g_0, e_0, c_0]} + 1) dP(g|c) \approx e^{-g_0\gamma_1 + (e - e_0)\gamma_2 - g_0e_0\gamma_3 + (\gamma_1 + e\gamma_3)(\alpha_0 + \alpha_1 c) + \frac{1}{2}(\gamma_1 + e\gamma_3)^2\sigma^2} - e^{-g_0\gamma_1 - g_0e_0\gamma_3 + (\gamma_1 + e\gamma_3)(\alpha_0 + \alpha_1 c) + \frac{1}{2}(\gamma_1 + e\gamma_3)^2\sigma^2} - e^{(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3 + 1}$.

2.2. Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

Let $RR_{g_1e_1} = \frac{E[Y|g_1, e_1, c]}{E[Y|g_0, e_0, c]}$. For the three-way decomposition of the joint excess relative risk of both exposures, $RR_{g_1e_1} - 1$, we have the decomposition:

$$(RR_{g_1e_1} - 1) = (RR_{g_1e_0} - 1) + (RR_{g_0e_1} - 1) + (RR_{g_1e_0} - RR_{g_0e_1} - RR_{g_1e_0} - RR_{g_0e_1} + 1).$$

Under the logistic regression model with a rare outcome

$$
\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 g e + \gamma_4 c,
$$

the proportions of the joint excess relative risk of both exposures due to each of the exposures considered alone and due to interaction can be estimated approximately by:

$$
\frac{RR_{g_1e_0} - 1}{RR_{g_1e_1} - 1} \approx \frac{e^{(g_1 - g_0)\gamma_1 + (g_1 - g_0)e_0\gamma_3} - 1}{e^{(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3} - 1},
$$

$$
\frac{RR_{g_0e_1} - 1}{RR_{g_1e_1} - 1} \approx \frac{e^{(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3} - 1}{e^{(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3} - 1},
$$

$$
\frac{RR_{g_1e_0} - RR_{g_0e_1} - RR_{g_0e_1} + 1}{RR_{g_1e_1} - 1} \approx \frac{e^{(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3} - e^{(g_1 - g_0)\gamma_1 + (g_1 - g_0)e_0\gamma_3} - e^{(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3} + 1}{e^{(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3} - 1}.
$$

2.3. SAS and Stata Code to Implement Proportion of a Total Effect Attributable to Interaction

Although we could obtain analytic standard errors for the expressions in Section 2.1 using the delta, the formulae would be very involved. The SAS procedure proc nlmixed, can however, carry out standard error computations for these expressions.

To estimate the proportion of the total effect of E on binary outcome Y due to E when G is fixed to g_0 and the proportion due to interaction when G is binary, and logistic regression model (A1) is used, one can use the code below. Suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and
three covariates ‘c1’, ‘c2’ and ’c3’. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G (‘g1=’ and ’g0=’) and the two levels of E (‘e1=’ and ’e0=’) that are being compared. The user must also input in the third line of the code the prevalence of the exposure G (‘pg=’) conditional on C = c (or use the marginal prevalence of G as a summary). In a case-control study, these prevalences should be computed only among the controls. For the standard error to be valid it is assumed that the prevalence of G is known; alternatively, standard errors and confidence interval can be interpreted as that for the proportion attributable to interaction in a population which had the same underlying risk ratios as the sample in question, but had a prevalence of G equal to the prevalence of G in the sample.

The output will include the proportion of the total effect of E that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to E when G is set to g0.

```sas
proc nlmixed data=mydata;
parms b0=1 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0;
g1=1; g0=0; e1=1; e0=0; pg=0.5;
p_y=(1-exp(-(b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3))))**-1;
ll_y= y*log (p_y)+(1-y)*log(1-p_y);
model Y ~general(ll_y);
estimate 'PAI_E' (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3)-exp((g1-g0)*b1+(g1-g0)*e0*b3)-exp((e1-e0)*b2+(e1-e0)*g0*b3)+1)*pg
/ ( ( exp((e1-e0)*b2+(e1-e0)*g0*b3) - 1) + (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3)
-exp((g1-g0)*b1+(g1-g0)*e0*b3)-exp((e1-e0)*b2+(e1-e0)*g0*b3)+1) *pg);
run;
```

The equivalent Stata code would be:

```stata
generate g1=1
generate g0=0
generate e1=1
generate e0=0
generate pg=0.5

generate Ige = g*e

logit y g e Ige c1 c2 c3

nlcom (exp((g1-g0)*_b[g]+(e1-e0)*_b[e]+(g1*e1-g0*e0)*_b[Ige])-exp((g1-g0)*_b[g]+(g1-g0)*e0*_b[Ige])-exp((e1-e0)*_b[e]+(e1-e0)*g0*_b[Ige])+1)*pg/
( ( exp((e1-e0)*_b[e]+(e1-e0)*g0*_b[Ige]) - 1) + (exp((g1-g0)*_b[g]+(e1-e0)*_b[e]+(g1*e1-g0*e0)*_b[Ige])
-exp((g1-g0)*_b[g]+(g1-g0)*e0*_b[Ige])-exp((e1-e0)*_b[e]+(e1-e0)*g0*_b[Ige])+1) *pg);
```

To estimate the proportion of the total effect of E on binary outcome Y due to E when G is fixed to g0 and the proportion due to interaction when G is continuous, and logistic regressions models (A1) and (A2) are used, one can use the code below. Suppose we have a SAS dataset named 'mydata' with outcome variable 'd', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second, third, fourth and fifth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G (‘g1=’ and ’g0=’) and the two levels of E (‘e1=’ and ’e0=’) that are being compared. The user must also input in the third line of the code the value of the covariates C at which the proportion attributable to interaction is to be calculated (‘cc1=’, ’cc2’ and ’cc3=’). Alternatively the mean values of these covariates in the sample could be inputted on this line as a summary measure (in a case-control study, these means should be computed only among the controls).

The output will include the proportion of the total effect of E that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to E when G is set to g0.
To estimate the proportion of the joint effect of both exposures on binary outcome $Y$ due to each exposure alone and due to interaction, when logistic regression model (A1) is used, one can use the code below. We again suppose we have a SAS dataset named ‘mydata’ with outcome variable ‘y’, exposure variables ‘e’ and ‘g’ and three covariates ‘c1’, ‘c2’ and ‘c3’. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of $G$ (‘g1=’ and ‘g0=’) and the two levels of $E$ (‘e1=’ and ‘e0=’) that are being compared. The output gives the proportions due to $G$ alone, the proportion due to $E$ alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other.

### 2.4. SAS and Stata Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

The equivalent Stata code would be as follows (with the output first giving the proportion of joint effect due to $G$ alone, then due to $E$ alone, and then that due to their interaction):

```stata
generate g1=1
generate g0=0
generate e1=1
generate e0=0
generate Ige = g*e
logit y g e Ige c1 c2 c3
nlcom (exp((g1-g0)*_b[g]+(g1-g0)*_b[e]+(g1-e0)*_b[Ige])-1)/ (exp((g1-g0)*_b[g]+(e1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)/ (exp((g1-g0)*_b[g]+(e1-e0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
nlcom (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1) / (exp((g1-g0)*_b[g]+(g1-e0)*_b[Ige])-1)
nlcom (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1) / (exp((e1-e0)*_b[e]+(g1-g0)*_b[Ige])-1)
```

3. Continuous Outcomes and Binary or Continuous Exposures

3.1. Proportion of a Total Effect Attributable to Interaction

As discussed in the Appendix to the text, for continuous exposures, when the effect of $E$ on $Y$ is unconfounded conditional on $(C, G)$ then the total effect of $E$ on $Y$, $E[Y_{e1}|c] - E[Y_{e0}|c]$, could be decomposed into two components as: $E[Y_{e1}|c] - E[Y_{e0}|c]$

$$= E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c).$$

Under the linear model $E[Y|G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha_4 c, (A3)$

these two components are:

$$E[Y|g, e_1, c] - E[Y|g, e_0, c] = (\alpha_2 + g\alpha_3)(e_1 - e_0)$$

$$\int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c) = \alpha_3\{E[G|c] - g_0\}(e_1 - e_0)$$

and the proportion due to interaction is then $\frac{\alpha_3\{E[G|c] - g_0\}}{\alpha_2 + g\alpha_3 E[G|c]}$.

This decomposition above marginalized over the distribution $P(c)$ gives: $E[Y_{e1}] - E[Y_{e0}]$

$$= \int \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\} dP(c) + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c)$$

and under model (A3) the components are:

$$E[Y|g, e_1, c] - E[Y|g, e_0, c] = (\alpha_2 + g\alpha_3)(e_1 - e_0)$$

$$\int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c) = \alpha_3\{E[G|c] - g_0\}(e_1 - e_0)$$

and the proportion due to interaction is then $\frac{\alpha_3\{E[G|c] - g_0\}}{\alpha_2 + g\alpha_3 E[G|c]}$. In section 3.3 SAS code is given for this latter decomposition.

3.2. Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

As also discussed in the Appendix to the text, if the joint effects of $G$ and $E$ are unconfounded conditional on $C$ we can empirically decompose the joint effects of both exposures combined as follows:

$$E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c] = \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} + \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\}$$

$$+ \{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c]\} - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c].$$

We can then also compute the proportion of the joint effect due $G$ alone as $\frac{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$, due to $E$ alone as $\frac{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$, and due to their interaction as $\frac{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$. On a difference scale, under the linear model $E[Y|G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha_4 c$,
these three proportions are given by:

\[
E[Y|g_1,e_1,c] - E[Y|g_0,e_0,c] \quad \frac{(\alpha_1 + \alpha_3c_0)(g_1 - g_0)}{\alpha_1(g_1 - g_0) + \alpha_2(e_1 - e_0) + \alpha_3(g_1e_1 - g_0e_0)}
\]

3.3. SAS and Stata Code to Implement Proportion of a Total Effect Attributable to Interaction

To estimate the proportion of the total effect of \( E \) on continuous outcome \( Y \) due to \( E \) when \( G \) is fixed to \( g_0 \) and the proportion due to interaction, and logistic regression model (A3) is used, one can use the code below. Suppose we have a dataset named ’mydata’ with outcome variable ’y’, exposure variables ’e’ and ’g’ and three covariates ’c1’, ’c2’ and ’c3’. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the level \( g_0 \) to which \( G \) will be fixed (’g0=’) when carrying out the decomposition of the total effect of \( E \) into the proportion due to \( E \) when \( G \) is fixed to \( g_0 \) and the proportion due to interaction when \( G \). The user must also input in the third line of the code the mean value of \( G \) in the population (’exp=’). For the standard error to be valid it is assumed that the mean of \( G \) is known; alternatively, standard errors and confidence interval can be interpreted as that for the proportion attributable to interaction in a population which had the same underlying effects as the sample in question, but had a mean of \( G \) equal to the mean of \( G \) in the sample.

The output will include the proportion of the total effect of \( E \) that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to \( E \) when \( G \) is set to \( g_0 \).

```
proc nlmixed data=mydata;
parms b0=0 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 ss_y=1;
g0=0; exg=0.5;
u0_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
mu_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=-((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
model Y ~general(ll_y);
proc nlmixed data=mydata;
parms b0=0 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 ss_y=1;
g0=0; exg=0.5;
u0_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
mu_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=-((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
mue; model Y ~general(ll_y);
```

The equivalent Stata code would be:

```
generate go=0
generate exg=0.5

generate Ige = g*e
reg y g e Ige c1 c2 c3

nlcom (_b[Ige]*exg-g0)/(_b[e]+_b[Ige]*exg)
```

3.4. SAS and Stata Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

To estimate the proportion of the joint effect of both exposures on continuous outcome \( Y \) due to each exposure alone and due to interaction, when logistic regression model (A3) is used, one can use the code below. We again suppose we have a dataset named ’mydata’ with outcome variable ’y’, exposure variables ’e’ and ’g’ and three
covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G ('g1=' and 'g0=') and the two levels of E ('e1=' and 'e0=') that are being compared. The output gives the proportions due to G alone, the proportion due to E alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other.

```plaintext
proc nlmixed data=mydata;
parms b0=0 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 ss_y=1;
g1=1; g0=0; e1=1; e0=0;
mu_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=-(y-mu_y)**2/(2*ss_y)-0.5*log(ss_y);
model Y ~general(ll_y);
estimate 'PaG' (b1+b3*e0)*(g1-g0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
estimate 'PaE' (b2+b3*g0)*(e1-e0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
estimate 'Pa_INT' b3*(g1*e1-g1*e0-g0*e1+g0*e0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
run;
```

The equivalent Stata code would be as follows (with the output first giving the proportion of joint effect due to G alone, then due to E alone, and then that due to their interaction):

```plaintext
generate g1=1
generate g0=0
generate e1=1
generate e0=0
generate Ige = g*e
reg y g e Ige c1 c2 c3
nlcom (_b[g]+_b[Ige]*e0)*(g1-g0)/(_b[g]*(g1-g0) + _b[e]*(e1-e0) + _b[Ige]*(g1*e1-g0*e0) )
nlcom (_b[e]+_b[Ige]*g0)*(e1-e0)/(_b[g]*(g1-g0) + _b[e]*(e1-e0) + _b[Ige]*(g1*e1-g0*e0) )
nlcom _b[Ige]*(g1*e1-g1*e0-g0*e1+g0*e0)/(_b[g]*(g1-g0) + _b[e]*(e1-e0) + _b[Ige]*(g1*e1-g0*e0) )
```
